## ABSTRACT

We examine the effect of grain size on the dynamic failure of tantalum during laser-shock compression and release and identify a significant effect of grain size on spall strength, which is opposite to the prediction of the Hall-Petch relationship because spall is primarily intergranular in both poly and nanocrystalline samples; thus, monocrystals have a higher spall strength than polycrystals, which, in turn, are stronger in tension than ultra-fine grain sized specimens. Post-shock characterization reveals ductile failure which evolves by void nucleation, growth, and coalescence. Whereas in the monocrystal the voids grow in the interior, nucleation is both intra- and intergranular in the poly and ultra-fine-grained crystals. The fact that spall is primarily intergranular in both poly and nanocrystalline samples is a strong evidence for higher growth rates of intergranular voids, which have a distinctly oblate spheroid shape in contrast with intragranular voids, which are more spherical. The length of geometrically-necessary dislocations required to form a grain-boundary (intergranular) void is lower than that of grain-interior (intragranular) void with the same maximum diameter; thus, the energy required is lower. Consistent with prior literature and theory we also identify an increase with spall strength with strain rate from  $6 \times 10^6$  to  $5 \times 10^7 \text{ s}^{-1}$ . Molecular dynamics calculations agree with the experimental results and also predict grain-boundary separation in the spalling of polycrystals as well as an increase in spall strength with strain rate. An analytical model based on the kinetics of nucleation and growth of intra- and intergranular voids and extending the Curran-Seaman-Shockey theory is applied which shows the competition between the two processes for polycrystals.

## 1. Introduction

Spalling, the failure of matter by tensile pulses resulting from the interaction of stress waves, is of interest for a wide range of applications including ballistic impact, dynamic fragmentation in hypervelocity particle-target interactions, and optical and/or diagnostic equipment hazards inside laser chambers [1–4]. The phenomenon of dynamic failure by spallation is well known and has been reviewed in a number of contributions [4–7]. There have been extensive studies using the flyer-plate method to

determine spall strength and the corresponding mechanisms of failure in face-centered cubic (fcc) metals [8–12]. Studies of spallation in body-centered cubic (bcc) metals using laser-driven shock have more recently gained momentum, but much space remains for systematic studies at large strain rates and varying initial microstructure [13–19]. Presented herein are the results of an investigation on the effects of grain size and strain rate on the spall strength of tantalum, a model bcc metal. Specifically, the experiments were designed to evaluate differences in spall strength between single, poly, and nanocrystalline Ta at the extreme strain rates enabled by laser shock pulses. Of particular importance is the identification of the nucleation sites and the evolution of damage leading to spalling [20]. The experimental results are complemented by molecular dynamics simulation and

an analysis based on the Curran -Seaman-Shockey theory [21–23].

When a laser pulse irradiates the surface of a specimen, a high temperature and pressure plasma are generated. The rapidly expanding plasma induces a shock wave via the rocket effect; the shock wave travels through the specimen until reaching the rear free surface of the sample where release (rarefaction) waves are generated due to free surface boundary conditions. The interaction of the shock and release (rarefaction) waves generates tensile stresses within the sample. If the tensile pulse exceeds a critical threshold stress, the material undergoes dynamic failure, known as spalling [24–28]. Laser shock in combination with VISAR measurements has been successfully used to determine the spall strength of metals in the 0.1–10 ns time ranges.

Previous spall strength measurements of single and polycrystalline tantalum show a potential grain size effect [29]. So far there have been no comprehensive studies comparing single, poly and nanocrystalline tantalum spall strengths. Furthermore, there is limited experimental spall strength data for tantalum for ultrathin samples at strain rates above  $10^6 \text{ s}^{-1}$ . Recent works attempt to remedy this dearth of information [29–32].

In this work we aim to (1) compare the spall strengths of single, poly and nanocrystalline Ta laser shocked under the same conditions; (2) establish the effect of strain rate on spall strength; and (3) develop a mechanistic understanding of the processes involved in the tensile failure.

## 2. Experimental methods

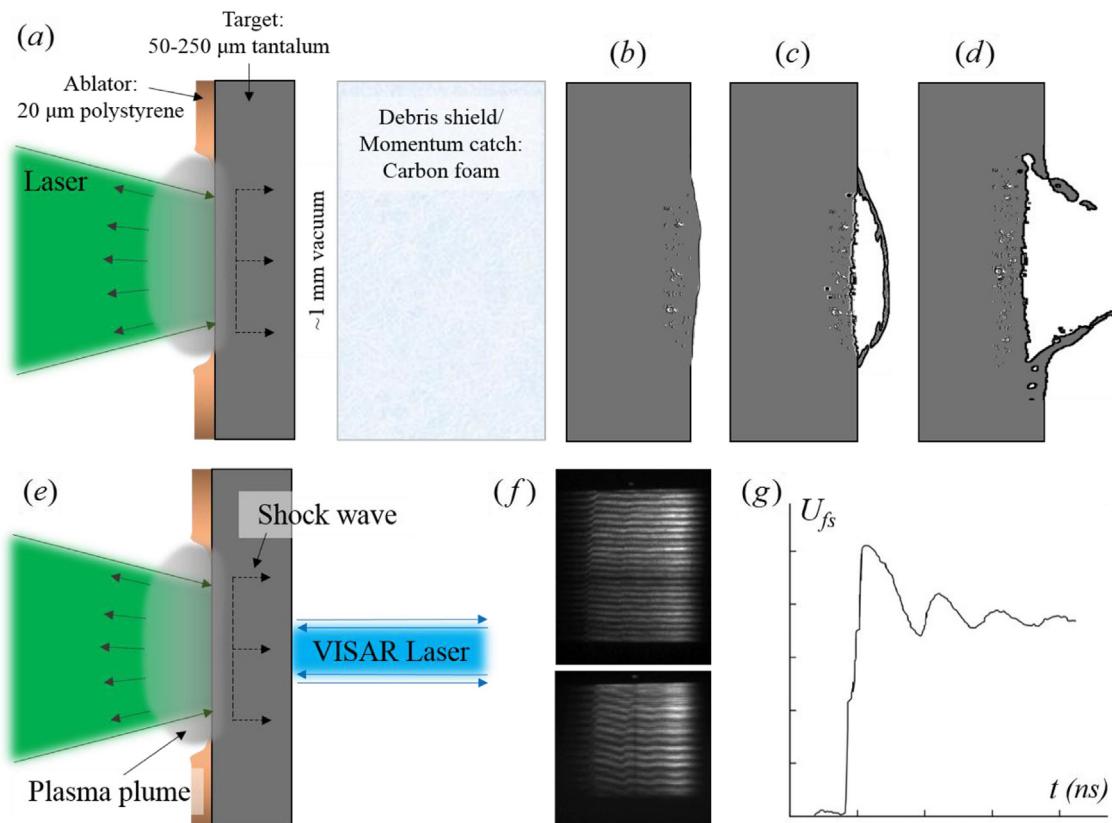

### 2.1. Materials and characterization

Monocrystalline tantalum samples were purchased from Marketech and polycrystalline Ta samples were acquired through the Lawrence Livermore National Laboratory (LLNL) national stock. The grain size of the polycrystal was measured under SEM observation to be  $\sim 20 \mu\text{m}$ . Nanocrystalline Ta samples were produced from the polycrystalline samples using high-pressure torsion (HPT) processing as previously described [33]. The HPT was conducted under quasi-constrained conditions [34] and produced an average grain size of  $\sim 100 \text{ nm}$  in the shock direction. An earlier report described the first comprehensive processing of Ta by HPT [35]. High-pressure torsion has been successfully used before to generate ultra-fine grained structure in tantalum, niobium, and tungsten [36–39].

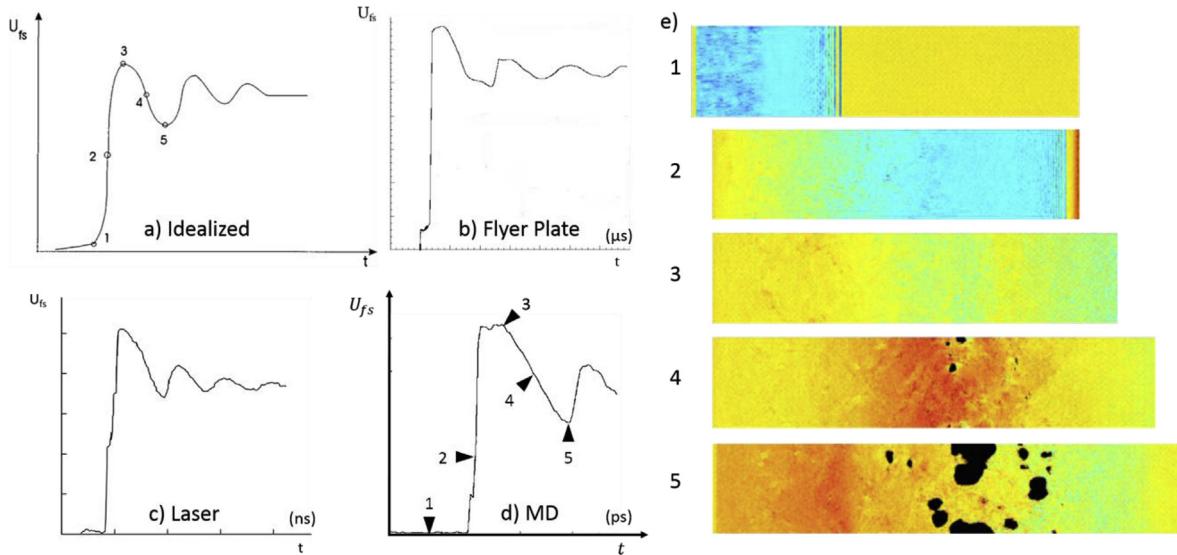

X-ray micro-CT was used to study fully contained spall voiding volumetrically and non-destructively. X-ray transmission microtomography was performed using a custom lab-scale instrument [40,41]. This system provided high X-ray energy for dense metal imaging and imaging resolution suitable to the study of microstructural features.

### 2.2. Experimental design

Nano, poly, and monocrystalline tantalum samples were cut by a low-speed diamond saw and mechanically polished to

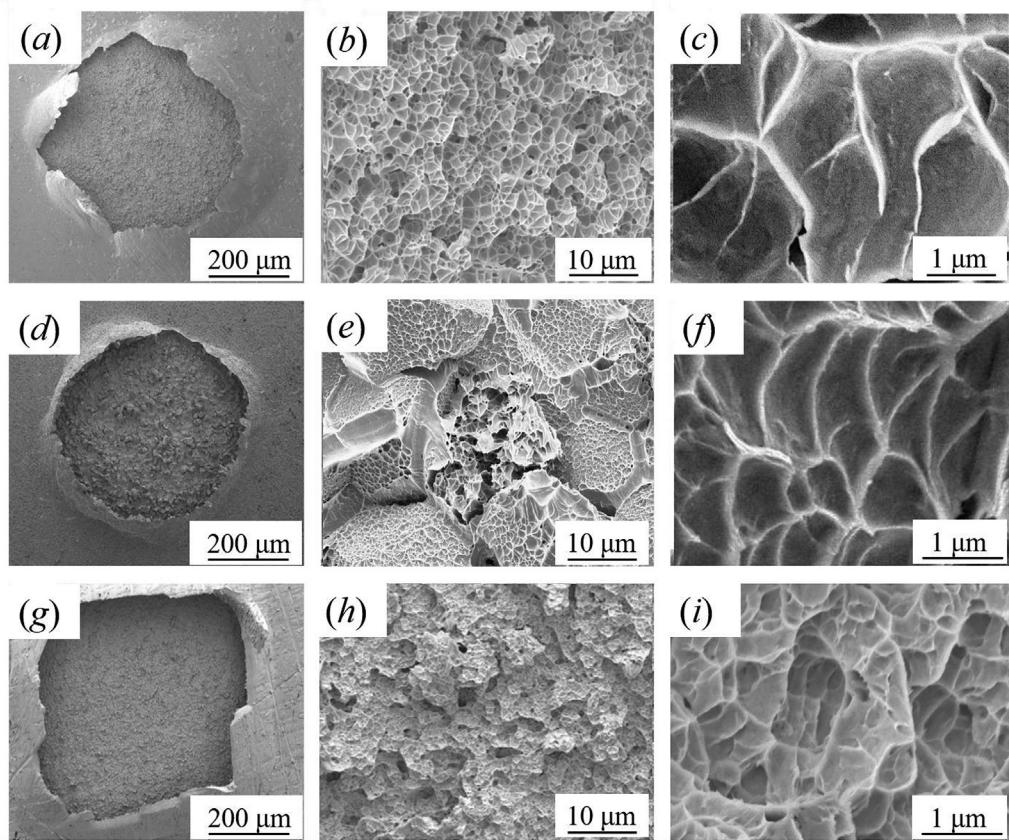

**Fig. 1.** Experimental setup schematic. Tantalum discs of thickness ranging from 50 to 250  $\mu\text{m}$  are covered by a 20  $\mu\text{m}$  ablator/heat shield and subject to laser ablation in order to drive a planar shock wave through the system. (a–d) Recovery experiments used a carbon aerogel foam to catch debris, decelerate and catch the tantalum for characterization. Depending on the laser energy, three states are expected (b) initial stages of incipient spall to identify void nucleation; (c) intermediate incipient spall where a clear spall bubble can be evaluated for void nucleation and growth; (d) complete spall failure. (e–f) VISAR analysis of free surface velocity. (f) Fringes are captured by a streak camera where Fourier analysis can transform this data into the form presented in (g). Experiments were conducted at the Janus laser facility, LLNL.

**Fig. 2.** Free (rear) surface velocity as a function of time for tantalum. (a) Idealized, (b) flyer plate impact, (c) laser driven, and (d) molecular dynamics simulation. Each trace shows qualitative similarities and (e) highlights processes occurring inside the material at five characteristic points. Notable, void nucleation (4) begins approximately halfway between the peak (3) and the pullback trough (5). The simulation is colored semi-qualitatively to the longitudinal shock stress state: blue is compression, red is tension, and yellow represents intermediate stress states. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

250  $\mu$ m and 50  $\mu$ m thickness. Samples were assembled by The Schafer Corporation, Livermore, CA using adhesive to attach a 20  $\mu$ m thick polystyrene ablator to one side. All glue was tacked on to the edges of the samples in order to minimize the gap between the polystyrene and sample surface. The polystyrene

layer acts as a heat shield for the tantalum samples and protects them against direct ablation and hot spots inherent in the laser energy profile. The experimental setup is displayed in Fig. 1. Recovery of laser shocked samples ranging from incipient to complete spall was enabled by an aerogel cylinder that

**Fig. 3.** SEM images at three magnifications of single (a–c), poly (d–f) and nanocrystalline (g–i) tantalum showing complete ductile spallation. Ductile failure is evidenced by the dimpling observed in (c, f, and i).

decelerated and caught the specimens in a recovery tube, Fig. 1a.

1-D radiation-hydrodynamic simulations (run using HYADES [42]) guided the experimental parameters of the laser energy, pulse shape, pulse duration, and sample thickness. Samples were laser shocked in the Janus laser chamber (a component of the Jupiter Laser Facility at Lawrence Livermore National Laboratory). Spall was generated in the mono, poly, and nanocrystalline Ta samples by laser shocking all the samples at the same laser energy, 100 J, and sample thickness, 250  $\mu\text{m}$ . HYADES simulations showed an increase in strain rate when sample thickness was reduced from 250 to 50  $\mu\text{m}$ . Single and nanocrystalline Ta samples with 50  $\mu\text{m}$  thickness were laser shocked at 75 and 100 J energy to test spall strength dependence on strain rate.

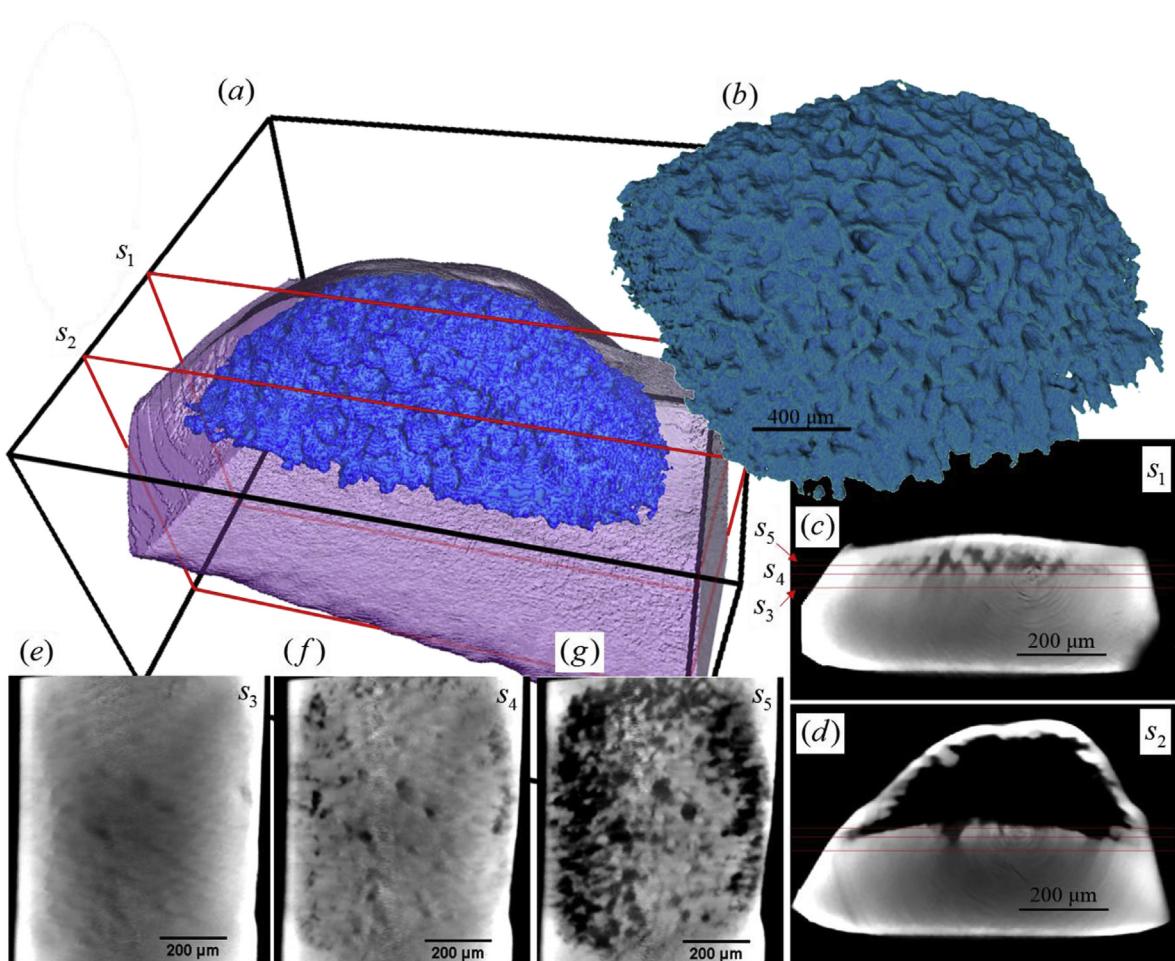

The velocity history of the free rear surface of the samples was recorded using VISAR [43], Fig. 1e. Data were collected for each laser shocked sample and processed to obtain the free surface velocity versus time profiles from which the spall strengths, peak pressures, and strain rates were extracted.

### 2.3. Micro-computed tomography

Using micro-CT, 3-D images of the voids in an incipient spall bubble were obtained for polycrystalline tantalum samples. A

250  $\mu\text{m}$  thick disk exhibiting a spall bubble was cut down to remove material around the bubble zone (~1 mm diameter) before conducting micro-CT scanning in order to improve the transmitted X-ray signal. The cut sample had a maximum width of ~800  $\mu\text{m}$ . The sample was seated on the micro-CT rotation stage using adhesive and mounted to a 1/8-inch aluminum post. X-ray imaging was conducted at 140 kV and 40  $\mu\text{A}$  target current using a reflection style tungsten target and the custom X-ray detector. X-ray projections were acquired in  $512^2$  pixel format at unique and periodic 0.5° increments over a 180° range. The distance from the X-ray spot to the sample was roughly 7.5 mm and an X-ray magnification factor of 9.76x was used. Reconstructions were performed using a fast Fourier transform MATLAB implementation of the Feldkamp-Davis-Kress filtered back projection cone-beam tomography algorithm and Hann filter. The effective voxel size in the reconstruction volume was 1.96  $\mu\text{m}$ .

In order to characterize the spall failure using X-ray micro-CT, the 2-D slices of tantalum had to be segmented. A non-local means (NLM) filtering followed by a simple threshold was used to obtain the segmented images. NLM filtering and segmented volume rendering were performed in Avizo Fire (FEI).

**Fig. 4.** Segmented 3D volume derived from  $\mu$ -CT imaging of the polycrystalline tantalum system subjected to spall conditions where the transparent purple is the tantalum and the solid blue material is the contained void. The surface of the spall bubble is shown in (b). (c,d) Cross sections identified in (a) showing (c) a view through the lateral edge of the spall bubble and (d) the center of the spall bubble. In (c, d) there is clear evidence of failure at grain boundaries by the presence of intact grains at the top and bottom of the bubble. Three “depth” progression views (e–g) correspond to the red lines of (c, d), lying parallel to the spall plane. Starting (e) near the edge of the spall bubble just within the tantalum and going (f), 30  $\mu\text{m}$  toward the bubble from part ‘e’, and (g) 50  $\mu\text{m}$  toward the bubble from part ‘e’. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

## 2.4. Spall strength calculation

The acoustic approximation simplifies the integrated equations of motion by considering the shock and release waves weak so that their velocities are approximated as the sound velocity [44]. The acoustic approximation is:

$$P_{\text{spall}} = (1/2)\rho_0 c(u_{\max} - u_{\min}) \quad (1)$$

where  $\rho_0$  is the initial density of the material,  $c$  is the sound velocity,  $u_{\max}$  is the peak velocity of the free rear surface (shock breakout), and  $u_{\min}$  is the first minimum velocity (spall pull-back) [45,46].

**Fig. 2** shows free surface velocity traces of an ideal ductile spall curve [44], flyer plate [47], laser-driven system, and molecular dynamics simulation [19] with excellent qualitative agreement across methods. We employ molecular dynamics simulations to visualize the internal stress states and void development relative to a free surface velocity trace for illustrative purposes. The simulation was carried out for a single crystal sample using LAMMPS [48] and employed an interatomic potential developed for tantalum under shock conditions by Ravelo et al. [49]. Details of the methodology are provided in previous literature [18,19]. Points 1–5 correspond to the molecular dynamics curve in **Fig. 2d**. Point 1 indicates the stationary free surface while the compressive wave traverses the sample. Point 2 indicates the rapid shock rise shortly after the arrival of the shock wave, and right below this point is the typical kink indicative of the Hugoniot elastic limit. Point 3 corresponds to the maximum rear surface velocity,  $u_{\max}$ , and marks the start of

relaxation [50]; the rarefaction wave begins returning into the sample at the beginning of the preceding plateau and, for short pulse durations, the width of the plateau approaches zero. Point 4 is the material undergoing tension at the spall plane. Point 5 is the arrival of the plastic release wave at the rear surface and marks the minimum rear surface velocity,  $u_{\min}$  [51]. **Fig. 2e** qualitatively illustrates the material response at characteristic times during spallation in tantalum. Since all of the present microscopy is conducted post-mortem, many challenges exist in correlating the final microstructure to the different stages of the dynamic spall process.

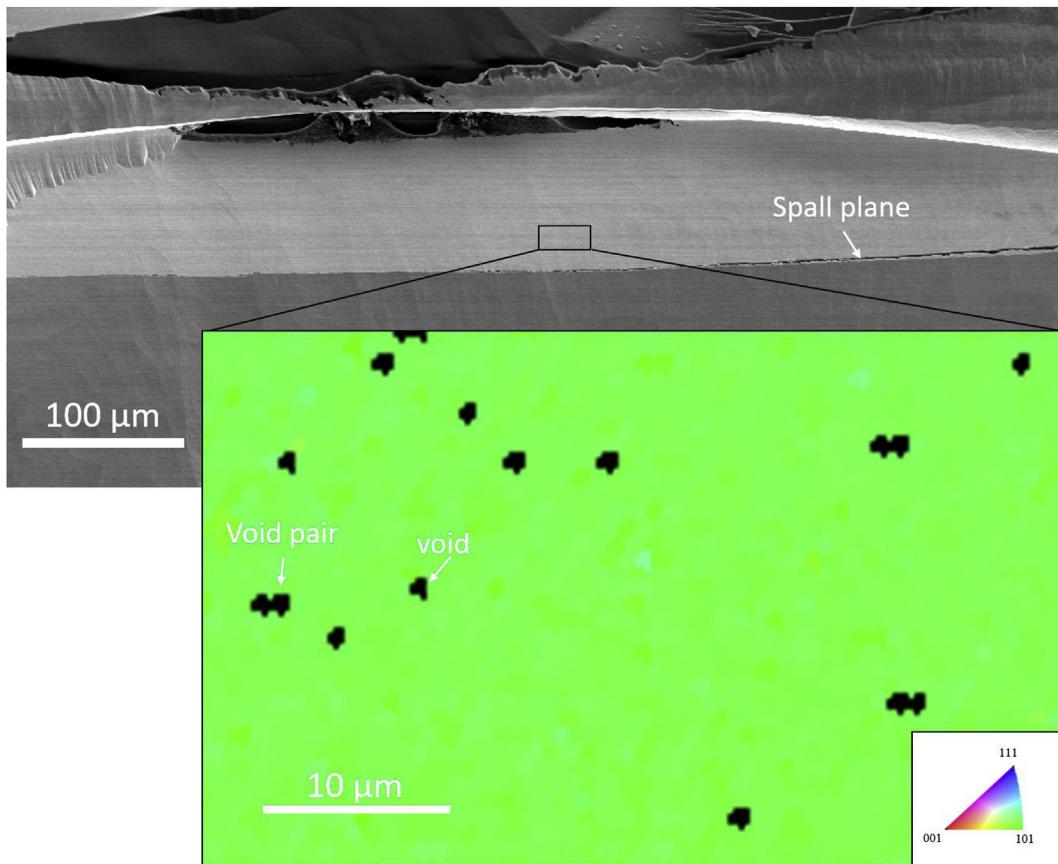

The strain rates were calculated by applying a classical acoustic approximation:

$$\dot{\epsilon} = \frac{(u_{\max} - u_{\min})}{(\Delta t \times 2c)} \quad (2)$$

where  $\Delta t$  is the time difference between  $u_{\max}$  and  $u_{\min}$  from the VISAR plot. The experiments used two specimen thicknesses, 250 and 50  $\mu\text{m}$ , and yielded strain rates of approximately  $6 \times 10^6$  and  $5 \times 10^7 \text{ s}^{-1}$ , respectively. By reducing the sample thickness, the strain rate is increased by a factor of ten.

## 3. Results

Spalled samples were characterized by SEM and micro-CT scans to identify the mechanisms of failure. SEM images of single, poly and nanocrystalline Ta show dimpling on the surfaces which strongly suggests that tantalum spalled by ductile failure (**Fig. 3**). Monocrystalline tantalum failed by the nucleation, growth and

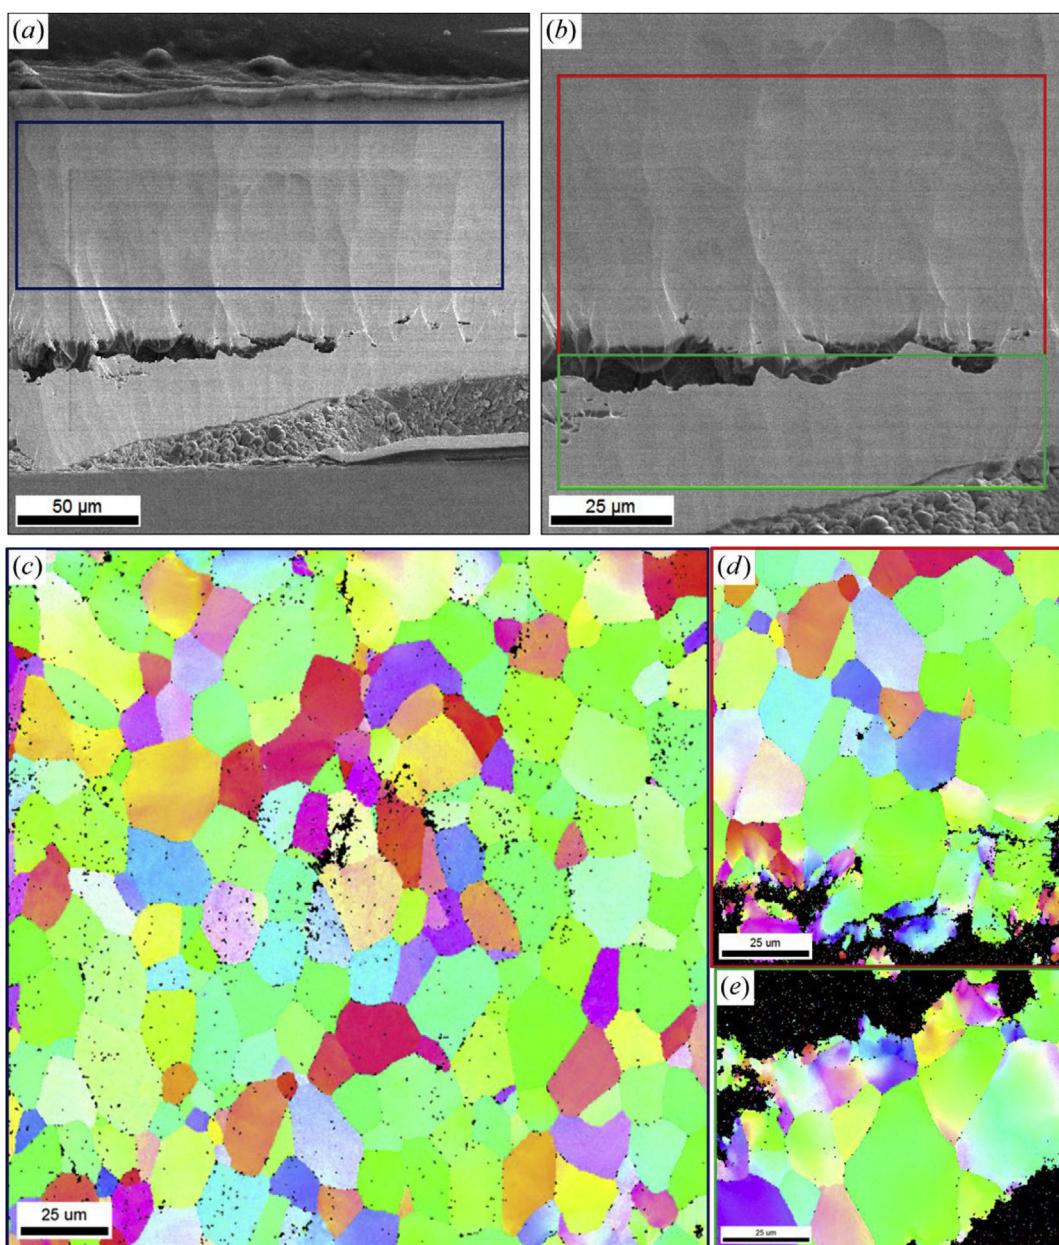

**Fig. 5.** Microstructural analysis of spalling in monocrystalline tantalum. The secondary electron SEM image on top shows the spall plane in the bottom of sample. The EBSD mapping (IPF) below shows randomly distributed voids in the vicinity of the spall plane; their spacing is approximately 10  $\mu\text{m}$ .

coalescence of voids in the spall plane, Fig. 3a–c. Voids may grow from any inclusions or impurities or simply from mechanical twins or high dislocation concentrations in specific regions. On the other hand, both poly and nanocrystalline Ta were observed to have substantial intergranular voiding. This is clearly seen in the relatively coarse-grained polycrystalline material, Fig. 3d–f.

### 3.1. Micro-computed tomography

Micro-CT reconstructed images of a plane sectioning the spall bubble, perpendicular to the rotation axis of the scan, are provided in Fig. 4. Bright light phases correspond to those which are highly attenuating (tantalum) and the dark phases correspond to those which are lowly attenuating (air/voids). Several reconstruction

artifacts present in the dataset can be seen in Fig. 3. The brightening of the periphery, or the darkening of the interior, is known as beam-hardening induced intensity cupping and is a result of the polychromatic X-ray beam used for attenuation imaging [52,53]. Also, ring-like artifacts are observed, which are essentially the result of sensor miscalibration or beam instability [54]. In addition to the spall bubble volume itself, nodular features at the interior of the void's surface are observed. The nominal size of these features is comparable to the grain size observed via SEM (Fig. 3e), indicating that the tortuous surface is principally attributed to grain-boundary separation and demonstrates that the grain boundaries are weaker, at the imposed strain rates, than the bulk material. The spalled area has a square shape, which is due to the phase plate used to homogenize the laser energy distribution. The area of the phase plate

**Fig. 6.** Microstructural analysis of polycrystalline tantalum spallation. The marked rectangular regions in (a,b) correspond to (c,d,e). (c) Away from the spall bubble, incipient spall can be seen as voids scattered throughout the specimen. The EBSD scans show the voids at the grain boundaries as well as grain interiors. (d,e) The area directly beneath the spall bubble shows smaller grain sizes at the edge of the spall bubble. This can be attributed to the following: the voids growing relatively large from the imperfection sites within the grains at some point grew into the coalescing large voids growing at the grain boundaries. Once a large enough perforation was formed, the material was pulled off (spalled off) leaving behind remnants of the grains, which are thus rotated and appear smaller in size than the average grain size of ~20  $\mu\text{m}$ .

is  $1\text{ mm}^2$ , which approximately corresponds to the size of the spall.

A virtual cross section of the sample near the edge of the bubble feature is provided in Fig. 4c, where the nodules of the opposing sides appear to have at one point been continuous. The selective separation of certain grain boundaries re-emphasizes that microstructure plays an important role in the failure of tantalum. Fig. 4d contains a cross section near the center of the bubble, where one particularly large nodule (grain) can be seen to correspond with a dimple of similar size on the opposing surface, quite probably where the grain was positioned prior to spalling. The spall bubble was also observed to be bound at the periphery through grains acting as branching ligaments in the spall plane, as shown in Fig. 4b (intact ligaments can be seen).

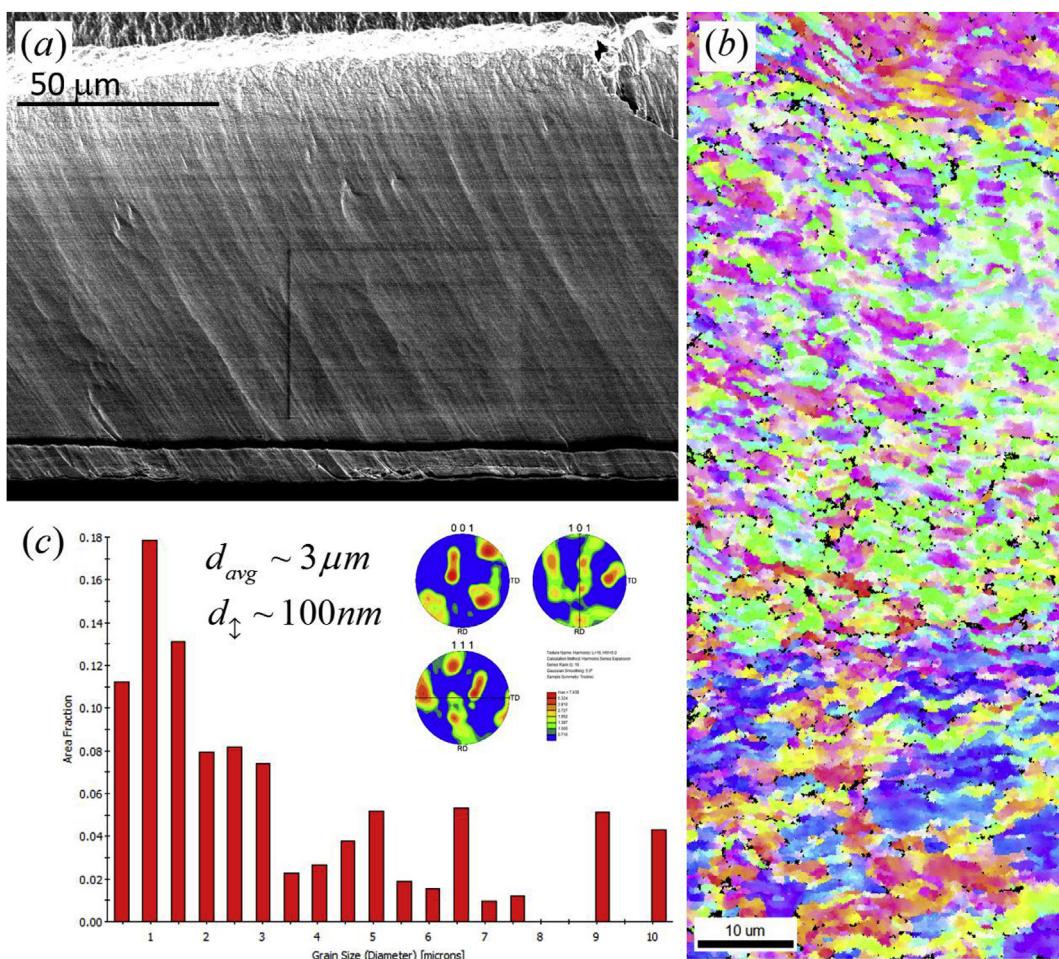

Micro-CT images also revealed microvoids in the spall zone of polycrystalline tantalum. Fig. 4e–g are provided to demonstrate the 3-D information contained within the CT dataset, wherein artificial sections are taken through the dataset at decreasing proximity from the spall bubble. Similar to the SEM observations, micro-CT imaging indicated intergranular voiding mechanisms that were active in the spalling of granular tantalum.

The segmented volume offered more manageable interpretation, quantification, and visualization than the grayscale volume.

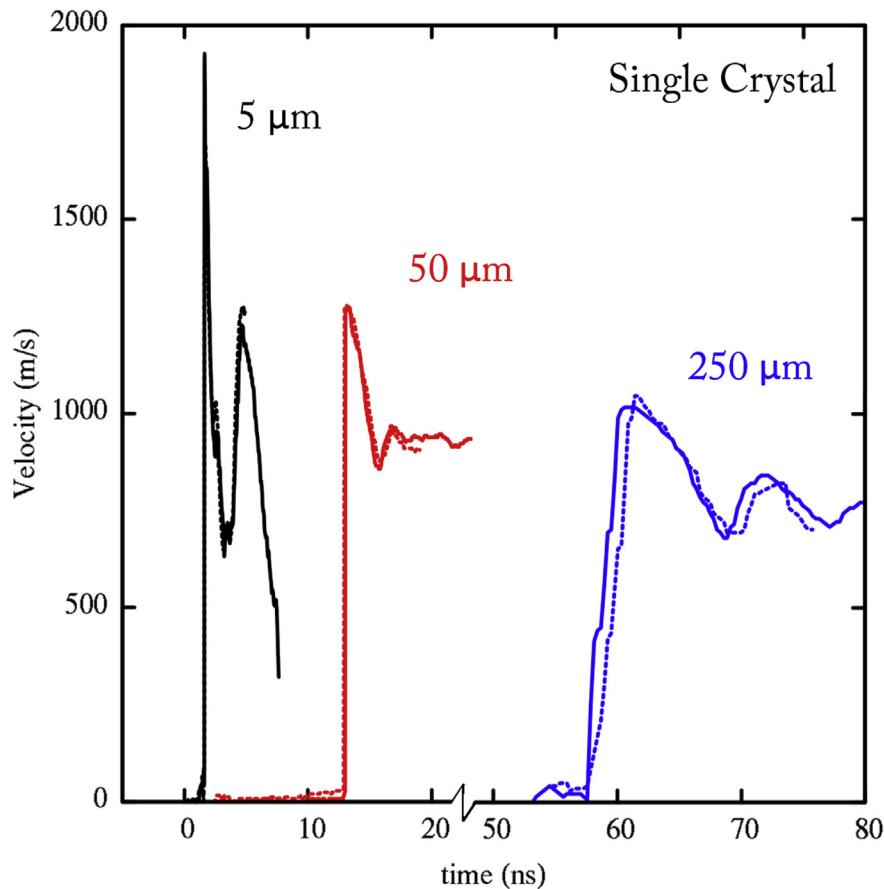

Fig. 4a–b contain renderings of the segmented 3-D volume derived from micro-CT imaging of the polycrystalline tantalum sample subjected to spall conditions. The rough spall surface indicates that a large quantity of free surface area was created during separation.

### 3.2. Microstructural characterization in the vicinity of the spall plane

To understand the influence of the microstructure on the dynamic failure of tantalum, scanning electron microscopy (SEM) and electron backscattered diffraction (EBSD) characterization was performed on the cross section of the as-shocked monocrystalline (Fig. 5), coarse-grained polycrystalline (Fig. 6), as well as ultrafine grained specimen (Fig. 7). For the monocrystalline sample, profuse voids have been identified in the vicinity of the spall plane. These voids have a spacing of approximately  $10\text{ }\mu\text{m}$  and diameters less than  $1\text{ }\mu\text{m}$ . Molecular dynamics simulations by Traiviratana et al. [55] revealed (their Fig. 8), albeit at a much smaller scale, geometrical facets acquired by void formation in copper. In fcc metals, voids have been observed to have faceted sides by virtue of the anisotropy of flow stress [5,55]. However, the present results do not show this deviation from sphericity because the size of the

**Fig. 7.** Microstructural analysis of nanocrystalline tantalum spallation. (a) The bottom surface shows a separation of the material. This separation suggests the voids that nucleated and had enough time to grow and coalesce into a large void volume. (b) In the adjacent region, the majority of voids can be found at nanocrystalline grain boundaries. From the scan, void nucleation, coalescence, and void clusters are most abundant at the grain interfaces, yet no particular crystalline orientation seems prevalent. (c) Grain size distribution and inverse pole figure (IPF) scan inset. Though the average grain size is  $3\text{ }\mu\text{m}$ , the average grain size in the shock direction is  $100\text{ nm}$ . The IPF shows significant texture, but there is no pre-shock reference with which to compare texture evolution during the spall process.

**Fig. 8.** Free surface velocity traces for single crystals of varying thickness. 5  $\mu\text{m}$  data from experiments can be found in Zhao et al. [80].

voids is near the resolution limit of the present EBSD analysis.

For polycrystalline and nanocrystalline Ta, as shown in Figs. 6 and 7, respectively, the density of voids seems to be higher than that of the monocrystalline sample. EBSD mapping suggests that these voids are preferentially located at the grain boundaries, although some of them can be found in the grain interior as well. The fact that the fracture is primarily intergranular suggests that voids nucleate in greater proportion at the grain boundaries and grow faster at these locations.

### 3.3. Measurement of spall strength

Fig. 8 shows the velocity versus time profile for monocrystalline tantalum samples of varying thickness. Each sample has two curves, each corresponding to a VISAR trace. The degree to which they are consistent indicates that the data are conclusive and appropriately calibrated to each other and the experimental parameters. The strain rate and spall strength were calculated from these plots. The average spall strength for the 250  $\mu\text{m}$  thick monocrystalline tantalum sample was ~9 GPa and the average strain rate was  $\sim 6 \times 10^6 \text{ s}^{-1}$ . Also shown is a velocity versus time profile for the single crystal 50  $\mu\text{m}$  thick tantalum. Even thinner samples, ~30  $\mu\text{m}$  thick, were laser shocked at similar intensities, but were unable to be recovered due to total obliteration. The spall strength for the 50  $\mu\text{m}$  thick single crystal Ta sample was ~11.6 GPa with a strain rate of  $\sim 2.5 \times 10^7 \text{ s}^{-1}$ . Sample thickness has a strong influence on the strain rate: the 50  $\mu\text{m}$  thick sample achieved strain rates almost a 10-fold increase over that of the thicker samples of 250  $\mu\text{m}$ .

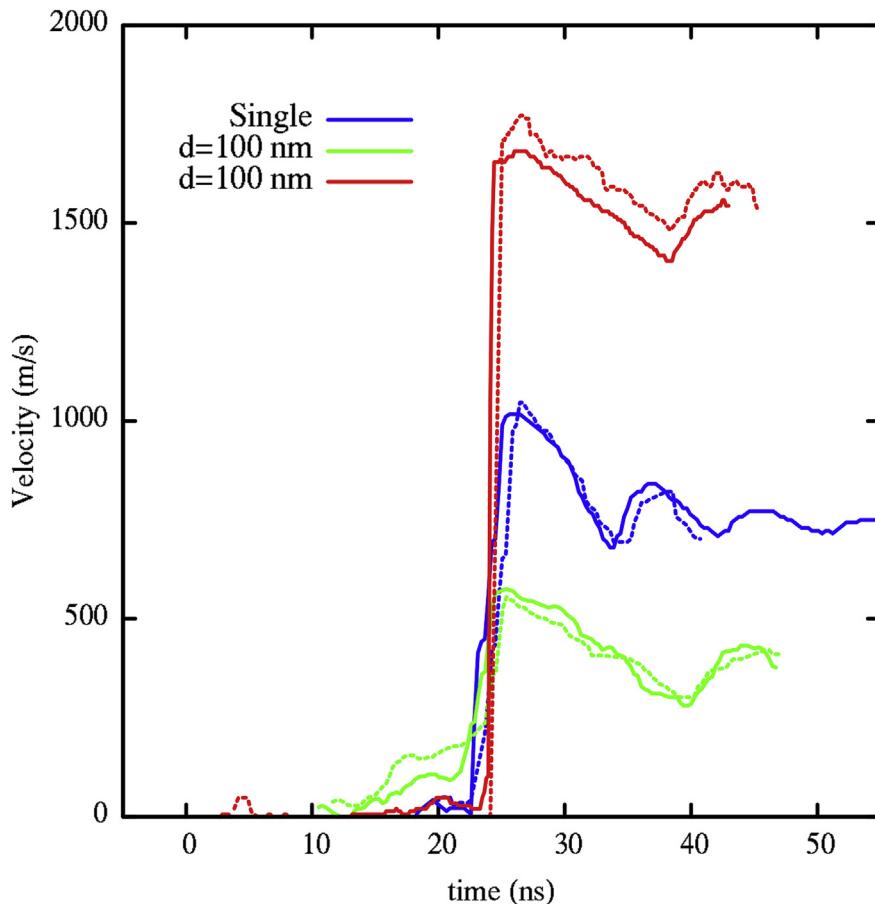

Free-surface velocity curves of single, poly and nanocrystalline Ta show a clear grain size dependency, as can be seen in Fig. 9. For a 250  $\mu\text{m}$  thick polycrystalline tantalum sample the calculated average spall strength is ~8.2 GPa and average strain rate  $\sim 5.5 \times 10^6 \text{ s}^{-1}$ . The calculated average spall strength of a 250  $\mu\text{m}$  thick nanocrystalline tantalum sample was ~7.0 GPa and the average strain rate was  $\sim 3.0 \times 10^6 \text{ s}^{-1}$ . Comparing these results (Fig. 10), single crystals have the highest spall strength, followed by polycrystals and nanocrystals, respectively. Spall strength was expected to be highest in single crystal and lowest in nanocrystal because voids nucleate, grow and coalesce preferentially (leading to failure and spall) along grain boundaries. The SEM images attest to this logic. Thus, it is clear that the single crystals exhibit the highest spall strength since they have the fewest grain boundaries (none), and nanocrystals have the most, which leaves polycrystalline Ta spall strength to fall somewhere between the two.

## 4. Discussion

It was shown in Section 3 that tantalum exhibits ductile fracture behavior under dynamic loading. The spall strength increases as a function of the strain rate whereas it decreases with grain size, in agreement with experimental results in the literature [29,56]. The results of both molecular dynamics calculations and analytical modeling will be presented in Sections 4.1 and 4.2, respectively.

### 4.1. Molecular dynamics predictions

Our experimental results are in good agreement with the spall

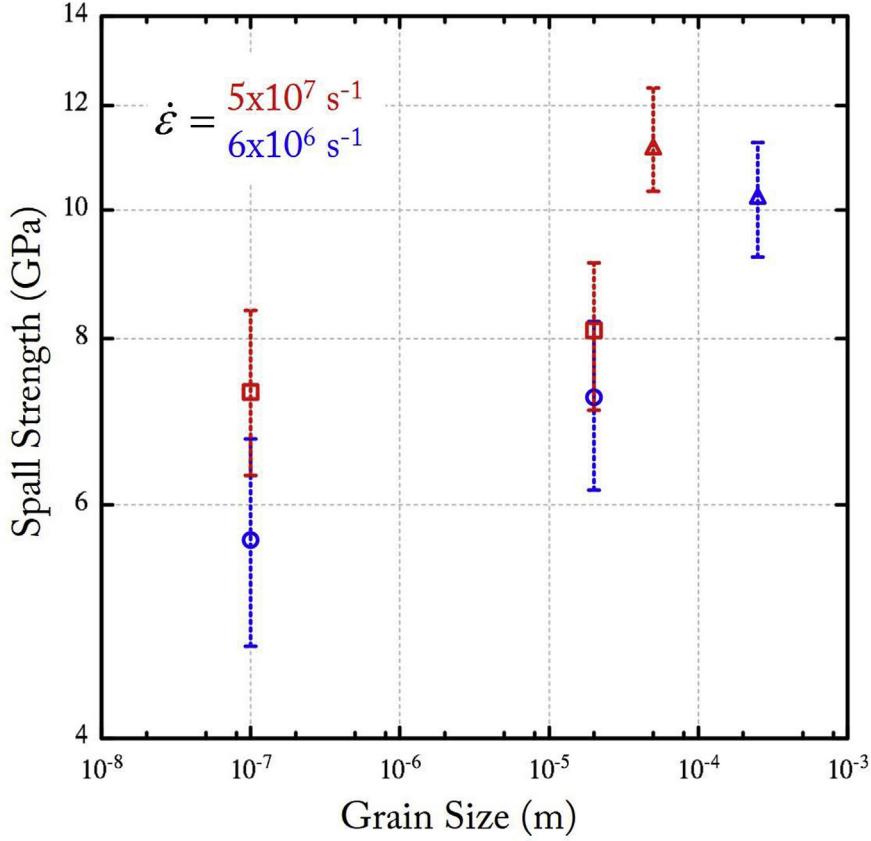

**Fig. 9.** Representative VISAR traces for single and nanocrystalline tantalum. Although the current experiments were not able to match the peak shock pressure between single and nanocrystalline samples, the two nanocrystalline traces show similar pullback behavior and a decrease in pullback amplitude as compared to the single crystal. This indicates that monocrystal tantalum has a greater spall strength than nanocrystalline tantalum.

strength versus strain rate plot, Fig. 11, which presents a broad range of both experimental and computational results. The open symbols represent the results of MD computations, which range from  $10^7$  to  $10^{12} \text{ s}^{-1}$ ; the closed circles come from a variety of sources, including flyer-plate experiments at the lower strain rates, and the results of the current research. The monocrystalline specimens show a higher spall strength, especially at the lower strain rates. The three lines for monocrystalline, polycrystalline, and nanocrystalline spall strength converge at  $10^{12} \text{ s}^{-1}$ , which is close to the Debye frequency, corresponding to the frequency of atomic vibration. This was analyzed by Hahn et al. [18] and potentially considered the ultimate tensile strength. There is a group of experimental results at  $10^{10} \text{ s}^{-1}$ , which show values clearly higher than the current measurements. Hahn et al. [18] also explained the differences between mono and nanocrystalline tantalum tensile failure through molecular dynamics. The presence of a grain boundary localizes the failure along the interface, although nucleation of voids also takes place in other regions. The growth is favored along the grain boundary, as can be seen in Fig. 12a. Different grains are identified by characteristic colors; the atoms are colored qualitatively according to their local crystalline orientation. A void growing along a grain boundary is visible. Fig. 12b shows the process of void coalescence in a monocrystal. Fig. 12c and d show dislocations (green lines) and the surface of voids (dark red) identified by DXA [53] and coordination algorithms respectively. The principal voids are also surrounded by smaller voids in both cases. Failure in the nanocrystalline sample is limited to the grain

boundaries, where the single crystal exhibits intragranular failure. The calculated spall strengths for nano and single-crystal tantalum at a strain rate of  $10^8 \text{ s}^{-1}$  are 8.5 and 13 GPa respectively. Thus, there is a significant reduction of spall strength when introducing a high volume fraction of boundaries.

#### 4.2. Analysis of void nucleation, growth, and coalescence

It is clear from the observations that nucleation of voids takes place both in the grain interiors and boundaries, with specific and distinct nucleation/growth rates. The kinetics of their growth is also influenced by the presence of grain boundaries. Both effects are evident in Fig. 6c. The nucleation occurs in both grain interiors and boundaries; however, the coalescence of voids occurs preferentially along grain boundaries, leading to an intergranular fracture. These two effects are described graphically in schematic fashion in Fig. 13, which shows sequences for void nucleation and growth in monocrystalline (Fig. 13a1-a4) and polycrystalline (Fig. 13b1-b4), tantalum subjected to dynamic tensile loading. In monocrystalline materials, the voids nucleate randomly in the grain interior and the growth requires the plastic deformation of its surroundings. The voids grow via the emission of dislocations from the void/matrix interface. The shadowed area in Fig. 13a1 illustrates the plastic zone in the vicinity of the void. Such voids are named intragranular. Voids continue to nucleate and grow in the material, resulting in a distribution of void sizes. Eventually, the voids coalesce and ductile failure takes place.

**Fig. 10.** Experimental data shows there is a correlation between spall strength and grain size in tantalum. As grain size increases, spall strength increases in Ta.

Void nucleation and growth at the grain boundaries is shown in Fig. 13b1-b4. The voids develop a non-spherical, oblate spheroid shape with the major axes aligned with the boundary plane. The plastic zone, for a specific diameter, tends to be smaller than for the intragranular voids. The energy required for intergranular void growth is thus smaller than that of for intragranular growth. Thus, as will be shown quantitatively later, intergranular voids dominate failure in polycrystalline materials.

The growth of voids is the result of shear and prismatic loop emission by a mechanism proposed by Lubarda et al. [57,58] and verified by molecular dynamics simulations in fcc and bcc metals [59,60]. The growth along grain boundaries proceeds by the same mechanism but the number of loops emitted is less because of differences in shape (oblate spheroid vs. sphere). Fig. 14a shows, in schematic fashion, the emission of shear and prismatic loops leading to the growth of voids in the grain interior.

It has been postulated analytically [57,58] and demonstrated by molecular dynamics calculations [e.g. [59–61]] that growth of spherical voids takes place by dislocation emission from the void surface. These shear loops eventually form prismatic loops by cross-slipping of the screw (lateral) component, as the (frontal) edge component advances. This is shown in Fig. 14. In fcc metals, where partial dislocations are emitted, this reaction does not take place. Fig. 14a shows the sequence of dislocation emission from a growing void in a bcc metal, starting with shear loops propagating in eight [111] directions and continuing with the formation of prismatic loops.

It is possible to equate the total length of dislocations to the volume of a void, and this has indeed been done by Ruestes et al. [62,63] and Hahn et al. [18]. The growth of a spherical void requires a greater dislocation length than an oblate spheroid with the same

radius R. The emission of dislocations from a growing intergranular void is qualitatively shown in Fig. 14b.

A quantitative evaluation of the kinetics of void nucleation and growth is presented next, starting with spheroidal intragranular voids and proceeding to intergranular voids. The Curran-Seaman-Shockey (CSS) theory [21,22] will be applied and extended to the polycrystalline regime. The number of voids in ductile metals is obtained from the nucleation rate per unit volume,  $\dot{N}$ , which was proposed by SSC to exhibit an exponential dependence and can be represented by:

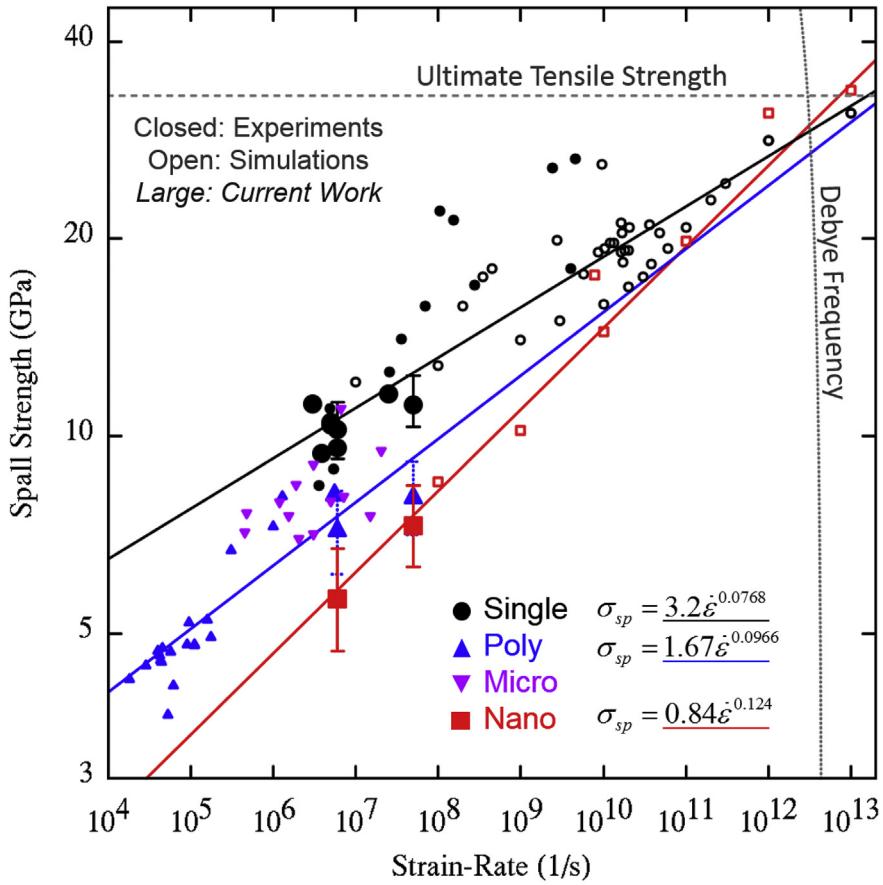

$$\dot{N} = \dot{N}_0 \exp\left(\frac{\sigma_m - \sigma_{no}}{\sigma_c}\right) \quad (3)$$

where  $\sigma_m$  is the tensile stress in the material,  $\sigma_{no}$  is the threshold stress for void nucleation,  $\dot{N}_0$  is a reference nucleation rate, and  $\sigma_c$  is a material constant. The nucleation of voids has been reported to occur preferentially at twin boundaries; these twins are generated by the compressive wave that precedes the tensile pulse [18,19,64–66].

In addition to void nucleation, void growth is another factor that determines the spall behavior of ductile metals. Assuming a spherical void with a radius of R, the growth rate is the time derivative of R, namely  $\dot{R}$ . Seaman et al. [67], proposed that the growth rate of the void is proportional to its radius R and is linearly dependent of the stress, above a threshold  $\sigma_{go}$ .

$$\frac{\dot{R}}{R} = k = \left(\frac{\sigma_m - \sigma_{go}}{4\eta}\right) \quad (4)$$

where  $\sigma_{go}$  is related to the stress for dislocation emission from an

**Fig. 11.** Spall strength as a function of strain rate plotted on a log-log scale. Power-law relationships are given for three “grain-sizes”: single crystals, polycrystals ( $d > 5 \mu\text{m}$ ), and nanocrystals ( $d < 500 \text{ nm}$ ) (no fit is given for microcrystals ( $500 \text{ nm} > d > 5 \mu\text{m}$ )). The ultimate tensile strength (UTS) of ~33 GPa is evaluated by Hahn et al. [18] using EOS and DFT data. The Debye frequency can be used as a predictor of what strain rate the material will reach the UTS and matches well with the power-law extrapolations. This graph illustrates the importance of the present nanocrystalline experiments in gaining insight into the grain-size dependent spall strength. Experimental data for large single and nanocrystalline samples (and thus lower strain rates) are absent from the literature. References as follows: Cuq-Lelandais et al. [30,81]; Soulard et al. [82]; Abrosimov et al. [56]; Ashitkov et al. [31]; Zhao et al. [80] citing unpublished results from C. Wehrenberg; Razorenov et al. [29]; T. Remington’s thesis [83]; Q. An et al. [84]; Gray et al. [47]; Zurek et al. [85]; G. Roy’s thesis [86]; Rivas et al. [87]; Glam et al. [88]; Millet et al. [89].

existing nucleus,  $\eta = \frac{\tau}{\gamma}$  is the material viscosity. Integrating Eqn. (4):

$$\dot{R}_i(t) = ke^{kt} \quad (5)$$

As the voids grow, new voids nucleate in the fraction of the volume occupied by solid matter. For simplicity, we assume that  $\sigma_{no} = \sigma_{go}$ . We define damage as the ratio between the volume of voids and the total volume:

$$D = \frac{V_v}{V_0} \quad (6)$$

We then apply an analysis similar to that of the Johnson-Mehl-Avrami-Kolmogorov (JMAK) equations [68–72]. There is a critical difference. Whereas the growth velocity is constant in the JMAK treatment, it increases exponentially with time here (Eqn. (5)). First, we consider an extended volume, assuming that it is completely solid and there is unlimited material available for voids to nucleate over the time interval  $0 < t < t$ . The volume fraction change per unit volume is:

$$\frac{V_v^e}{V} = \frac{4}{3}\pi N_o e^{\frac{\sigma - \sigma_{no}}{\sigma_c} k^3} \phi(t) \quad (7)$$

where  $\phi(t)$  is given by:

$$\phi(t) = \frac{1}{3k} \left[ \frac{2}{9k^3} + e^{3kt} \left( t^3 - \frac{t^2}{k} + \frac{2t}{3k^2} - \frac{2}{9k^3} \right) \right] \quad (8)$$

We now consider the entire volume of material that becomes voids, by subtracting the void fraction of voids. Thus, we obtain the corrected value  $dV_v$ :

$$dV_v = dV_v^e \left( 1 - \frac{V_v}{V_0} \right) \quad (9)$$

Integration and substitution into Eqn. (6) yields:

$$D = \frac{V_v}{V} = 1 - e^{\left[ -\frac{4}{3}\pi N_o e^{\frac{\sigma - \sigma_{no}}{\sigma_c} k^3} \phi(t) \right]} \quad (10)$$

The detailed derivation is given in the Supplementary Material section.

Parameters can be obtained from the experiments and from values used by Seaman et al. [67] to develop an analytical prediction of damage as a function of time. Some of these are discussed below. The spacing between both intergranular and intragranular voids can be inferred from the dimple size shown in Fig. 6. Each dimple corresponds to one-half of a void, the other being in the matching surface. For the polycrystalline (intergranular voids) and monocrystalline (intragranular voids) spall surfaces, the spacing is

$\sim 1 \mu\text{m}$ . This provides  $N = 1 \mu\text{m}^{-3}$ . The time  $t$  was taken as 10 ns. Thus, the initial nucleation rate  $\dot{N}_0 = N/t = 10^{-10} \text{ m}^{-3}\text{s}^{-1}$ . The spall strength in gas-gun experiments, in which the pulse time is 100 times larger (1  $\mu\text{s}$  vs. 10 ns) than laser experiments is equal to 4–6 GPa. This is used as a first estimate of  $\sigma_{n0} = \sigma_{go} = 4 \text{ GPa}$ . The normalizing parameter  $\sigma_c$  has to be evaluated from previous experiments by Seaman et al. [67]. This parameter has values of 0.2 GPa for copper and 0.04 GPa for Al. The former ( $\sigma_c = 0.2 \text{ GPa}$ ) is used for tantalum. The viscosity  $\eta$  was taken as 0.127 Pa.s $^{-1}$  and is extracted from molecular dynamics calculations for tantalum by Hahn et al. [13].

Coalescence of voids occurs when the void volume reaches a sufficiently large fraction. Deformation concentrates primarily in the ligaments between the voids. These eventually undergo necking and complete separation. We assume that this occurs at  $D = 0.5$ . Fig. 15a shows the application of Equation (10) to tantalum. The sigmoidal shape, characteristic of the JMAK equation, is apparent and is shown in Fig. 15a. Note that as the stress increases, the curve is translated to shorter times.

For intergranular voids, we use a similar approach as before, except we assume that the voids formed across grain boundaries are oblate spheroids (whereas before we assumed perfect spheres). As a result, we define damage in a slightly modified manner:

$$D = \frac{A_v}{A_0} \quad (11)$$

where  $A_v$  is the total area of intergranular voids in a grain-boundary surface area  $A_0$ . Intergranular void growth proceeds with the major axes of the oblate spheroid aligned with the grain-boundary plane. This opening along grain boundaries is the result of the competition between flow stress and grain-boundary cohesive strength, which have different strain rate sensitivities. It will be shown that the growth of a grain-boundary void requires less plastic deformation than that of a grain-interior void. The plastic deformation regions are schematically shown in Fig. 14b.

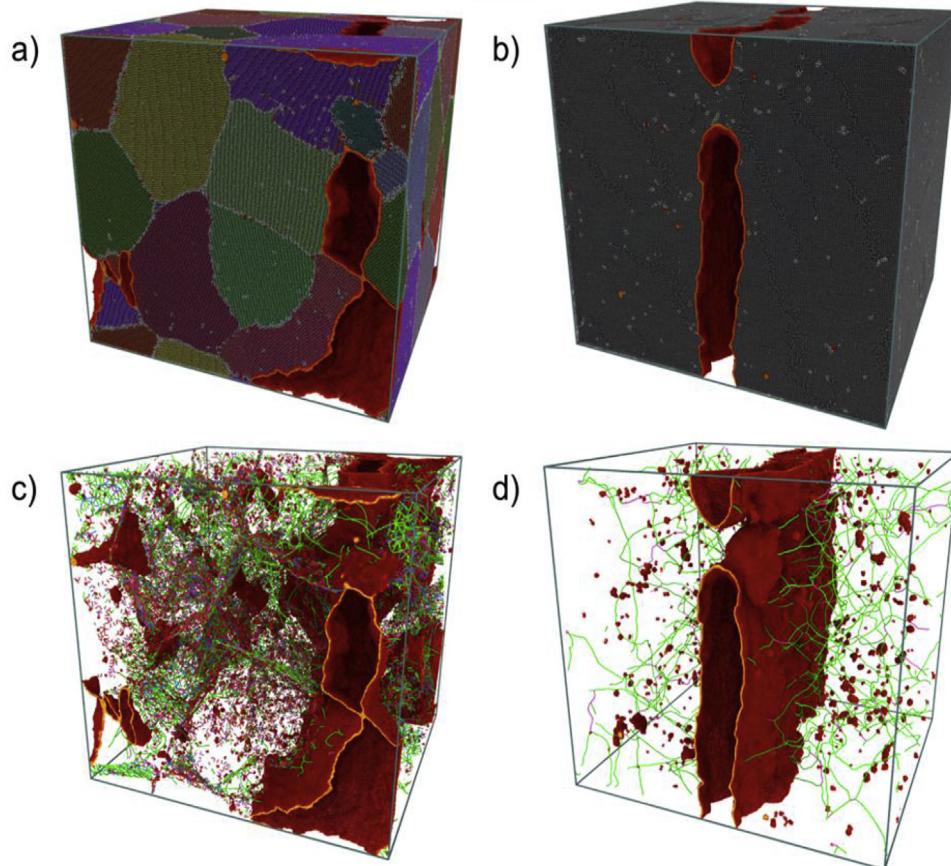

It is possible to use the concept of geometrically-necessary dislocations advanced by Ashby [73–75] to predict their density around a growing void. Traiviratana et al. [55], Ruestes et al. [62,63] and Hahn et al. [18] obtained expressions relating the growth of a void to the dislocation length generated by assuming an effective volume per dislocation equal to  $b^2$  per unit length:

$$dV = 4\pi R^2 dR \text{ and } dR = \frac{b^2 dL}{4\pi R^2} \quad (12)$$

where  $dL$  is the increase in the length of dislocation line.

Thus, for a radius  $R_f$  of a void:

$$L_f = \frac{4\pi}{b^2} \int_0^{R_f} R^2 dR = \frac{4\pi}{3b^2} R_f^3 \quad (13)$$

**Fig. 12.** Molecular dynamics snapshots of spall failure in nano- and single-crystalline tantalum. The loading direction is from the left to the right and the nominal strain rate is  $10^8 \text{ s}^{-1}$ . a,c) 25 nm nano-crystalline tantalum. b,d) Single-crystalline tantalum. The top row shows atoms colored according to their local crystalline orientation. The bottom row shows dislocations and the surface of voids identified by DXA [90] and coordination algorithms respectively. In both images the surface of voids are denoted by a dark red color. Failure in the nanocrystalline sample is limited to the grain boundaries, where the single crystal exhibits intragranular failure by necessity. The resulting spall strengths for nano and single-crystal tantalum at this strain rate are 8.5 and 13 GPa respectively – a 35% reduction of spall strength when introducing a high volume fraction of boundaries. (For interpretation of the references to color in this figure legend, the reader is referred to the Web version of this article.)

If one considers the plastic zone equal to  $nR$ , one can calculate the density of these geometrically-necessary dislocations:

$$\rho_{sphere} = \frac{3L_f}{(n^3 - 1)4\pi R_f^3} \quad (14)$$

Substituting Eqn. (13) into (14), we have:

$$\rho_{sphere} = \frac{1}{3b^2(n^3 - 1)} \quad (15)$$

For Ta, Hahn et al. [18] used  $b^2 = 0.106 \text{ nm}^2$  for dislocations under tensile loads. If one assumes that  $n = 3$ , a reasonable value for the work hardened zone, one obtains  $\rho = 4 \times 10^{17} \text{ m}^{-2}$ , a reasonable number for a severely hard-worked metal. This is on the same order of magnitude as the values obtained by MD and calculated by procedure above.

For an intergranular void, the volume is:

$$V = \frac{4}{3}\pi aR^2 \quad (16)$$

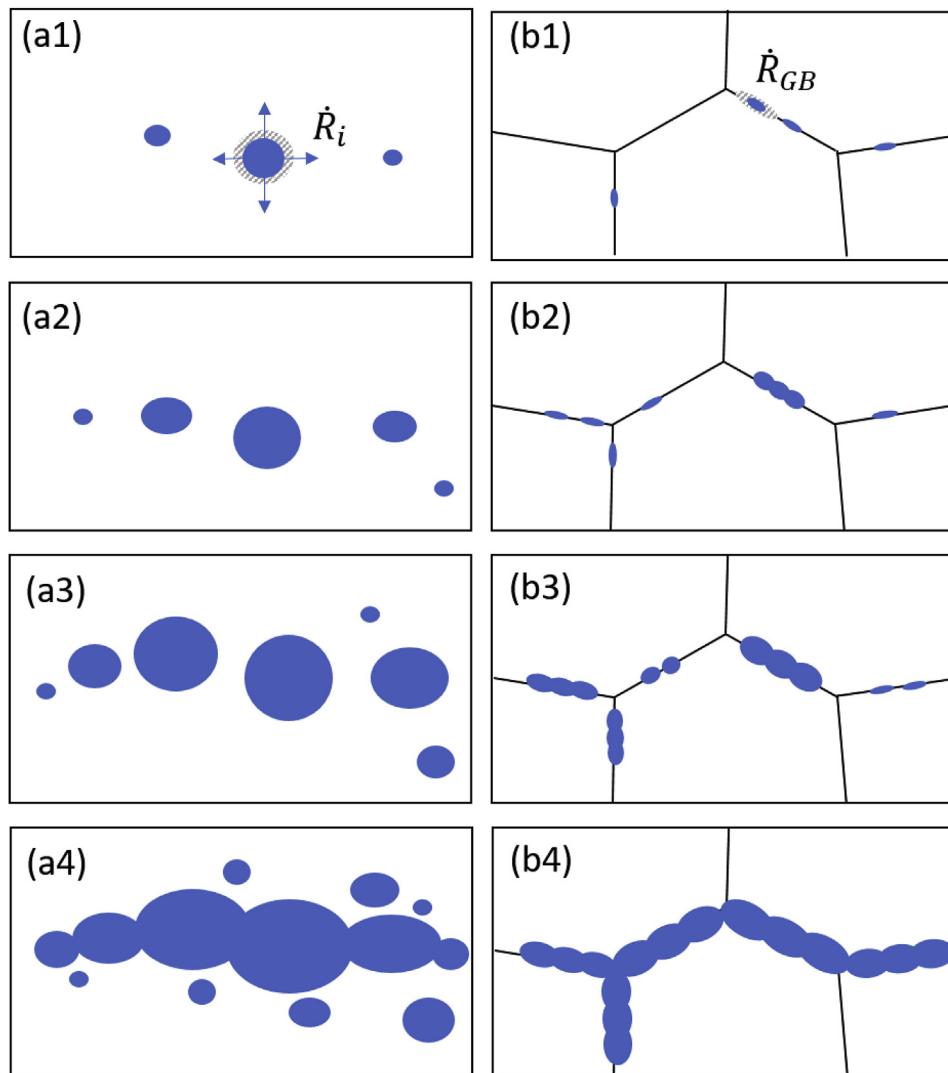

where  $a$  is the minor semi-axis of the oblate spheroid and  $R$  is its major axis. The dislocation density can be similarly be expressed as:

$$\rho_{spheroid} = \frac{a}{R}\rho_{sphere} \quad (17)$$

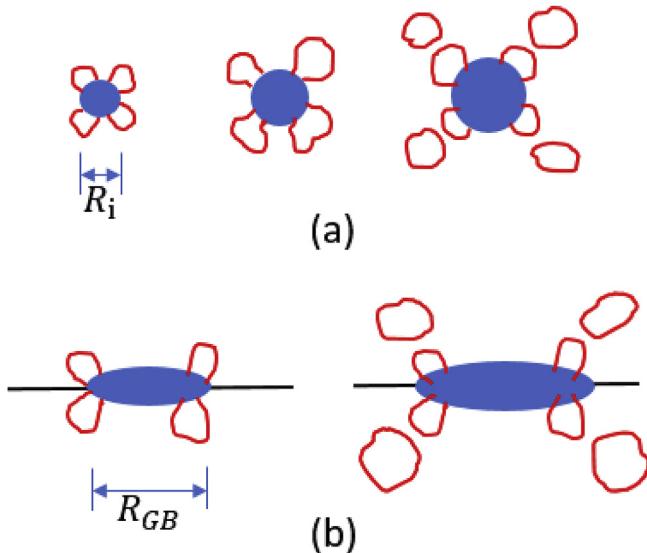

It is clear that the growth of grain-boundary voids requires less plastic deformation, and therefore less work, than that of grain-interior voids. We will use a simple expression relating the growth rate of the two types of voids; it essentially considers the rate of growth tied to the plastic work rate.

$$\frac{dR_{Gb}}{dt} = \frac{R}{a} \frac{dR_i}{dt} \quad (18)$$

Thus,

**Fig. 13.** Schematic drawings of the void nucleation, growth, and coalescence in monocrystalline (a1-a4) and polycrystalline (b1-b4) samples. In monocrystalline samples, voids nucleate in the grain interiors and grow via the emission of dislocations from the void/matrix interface. The shadowed area in Fig. a1 illustrates the plastic zone in the vicinity of the void. Such voids named are called intragranular. For nucleation of voids at grain boundaries (Fig. 13 b1), they tend to develop a non-spherical, oblate spheroid shape with the major axes aligned with the boundary plane. The plastic zone, for a specific diameter, tends to be smaller. The energy required for intergranular void growth is thus smaller than that of for intragranular growth. Therefore, intergranular voids dominate failure in polycrystalline materials.

**Fig. 14.** Schematic drawing of the void growth in grain interior and grain boundary. The emission of dislocations from these voids transports matter away from voids and creates a work hardened layer. (a) In the grain interior (and monocrystals), shear loops are emitted from the void surface and propagate along eight {111} directions; they expand and pinch out prismatic loops through cross-slip of the screw components. (b) In grain-boundary void growth, dislocations are emitted along the major spheroid circumference and slip away from the tip of the void, leaving multiple slip lines which sometimes can be experimentally observed (e.g. [91]).

$$R_{Gb}(t) = k't^{kt} \quad (19)$$

Where  $k'=(R/a)k$ . Considering self-similarity and a constant aspect ratio  $l=a/R<1$  for the oblate spheroid:

$$\frac{dA_v}{dt} = 2\pi Rl \frac{dR_i}{dt} \quad (20)$$

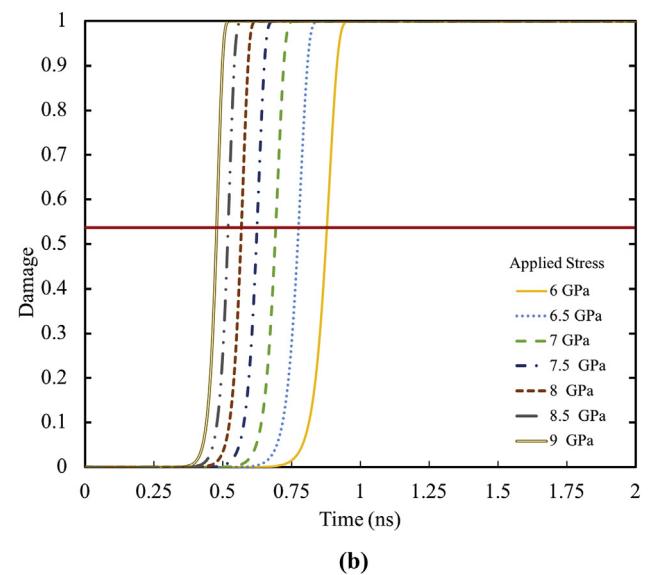

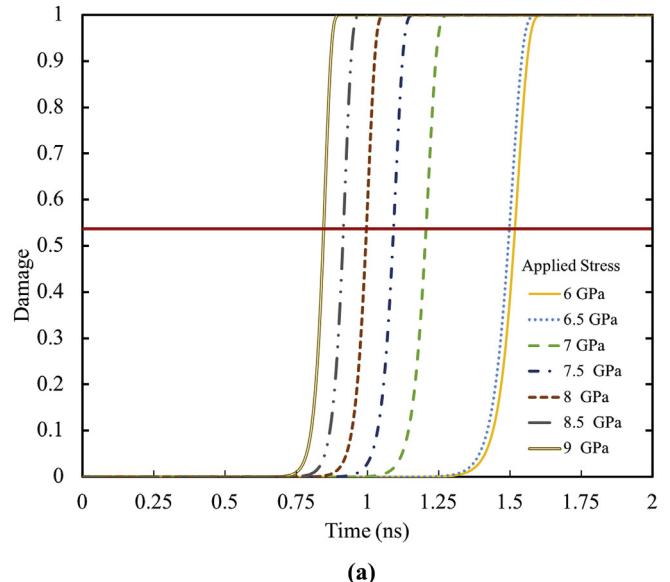

The procedure outlined in Eqns. (7)–(10) can be applied to the intergranular case. The initial nucleation rate was taken as  $N_0 = 10^{-4} \text{ m}^2 \text{s}^{-1}$ . We assume that  $R/a$  is 2, and account for the ratio of areas rather than volumes. A complete derivation can be found in the Supplementary Material section. Fig. 15b shows that intergranular void growth approaches failure ( $D = 0.5$ ) more quickly than intragranular growth (Fig. 15a).

By assuming spallation occurs at  $D = 0.5$ , the spall strength can be found and related to the strain rate. The corresponding spall strengths as a function of the tensile pulse duration are shown in Fig. 16. It is clear that, although the two mechanisms of intergranular and intragranular failure are operating, intergranular overtakes intragranular spalling and polycrystalline tantalum fails by grain-boundary separation. A corollary of this is that the monocrystalline tantalum exhibits a higher spall strength.

The strain rate can be obtained from the duration of the pulse by the application of the following expression from Reina et al. [76] and Hahn et al. [18] based on dimensional analysis:

$$\frac{de}{dt} = \frac{U_p}{tC_l} \quad (21)$$

where  $U_p$  is the particle velocity (dependent on pressure) and  $C_l$  is the longitudinal sound velocity (5400 m/s for Ta). The equation of state parameters used for the calculation of  $U_p$  as a function of pressure are obtained from Marsh [77]:  $U_s = 3.43 + 1.19 U_p$ . For the analysis performed, we obtain a strain-rate sensitivity at 0.51 for the intergranular case and 0.50 for the intragranular case. Although

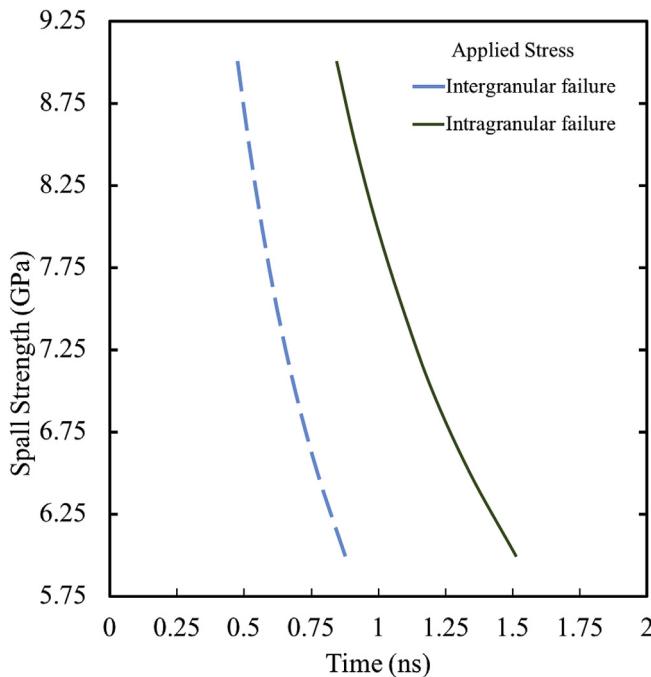

**Fig. 15.** Predicted evolution of damage as a function of time at different tensile stress levels for (a) intragranular and (b) intergranular void nucleation and growth.

these values are larger than those from molecular dynamics (Fig. 11), the current analysis applies to highly localized void growth and the values are dependent on the parameters chosen.

## 5. Conclusions

Mono, poly, and nanocrystalline tantalum spall by ductile failure. Voids nucleate, grow, and coalesce around grain boundaries in poly and nanocrystalline Ta; single crystalline Ta also shows signs of extensive dimpling but the voids are intergranular. At lower strain rates of  $10^6 \text{ s}^{-1}$  (250  $\mu\text{m}$  thick samples), single crystalline tantalum had the highest spall strength while nanocrystalline tantalum had the lowest, which has been explained by a rationale developed by Meyers [78]. The same sort of relationship has been observed in Cu [69] and V [79]. Polycrystals and nanocrystals contain boundaries, which act as heterogeneous nucleation sites for microvoids that nucleate and grow preferentially (along the grain boundaries) and, in the case of the polycrystals, may be related to the preferential

**Fig. 16.** Spall stress (defined as  $D=0.5$ ) as a function of time due to intragranular and intergranular void nucleation, growth, and coalescence. Note higher spall strength by ~2.5 GPa for monocrystalline vs. polycrystalline tantalum.

segregation of impurities at the grain boundaries. Indeed, the grain-boundary nucleation stress can be considerably lower than the bulk nucleation stress. The crossover between the curves marks the change in failure from bulk to intergranular. The volumetric analysis of the spall surface, performed nondestructively using X-ray micro-CT, supports the observations of the spall surface and confirms that the polycrystalline samples spall via intergranular void nucleation, growth and coalescence.

X-ray micro-CT has demonstrated a unique potential for characterizing the complex failure structures resulting from spall, even in the heavily attenuating tantalum system. Decreasing sample thickness (from 250 to 50  $\mu\text{m}$ ) resulted in higher strain rates (by ~10 fold) and spall strengths (~30% higher) than their thicker counterparts. Thus, a clear dependence of spall strength on strain rate and sample thickness was observed.

Molecular dynamics calculations predict spall strengths for mono and nanocrystalline tantalum, albeit at much smaller durations, that are consistent with the experimental results: the nucleation of voids occurs both inside (intragranular) and at the grain boundaries (intergranular), but the differences in the nucleation rates and growth rates lead to intergranular void coalescence and failure in the nanocrystalline specimens, with an attended decrease in the spall strength. The variation of the spall strength with strain rate for the three cases of mono, poly, and nanocrystals converge at strain rates of  $10^{12} \text{ s}^{-1}$ ; this is close to the Debye frequency, which is presumably the highest strain rate achievable.

The Curran-Seaman-Shockey theory for spalling in ductile materials is applied to the experimental conditions in the present work and extended for intergranular nucleation, growth, and coalescence of voids. This theory provides an analytical underpinning for the differences observed between mono and polycrystals and captures the principal features of the failure. The energy required to grow a grain-boundary void is lower than a grain-interior void. This can be explained in terms of geometrically-necessary dislocations. The length required to form a grain-boundary (intergranular) void with the

same maximum diameter. This explains the faster kinetics of growth for these voids, leading to a lower spall strength in polycrystalline tantalum.

In conclusion, a combined experimental-computational-analytical approach provides important new insights into the process of spalling in bcc metals, with tantalum as a model material.
